where α is the time step If the upstream machine is operational, it can fail in mode u_i with probability p_{u_i} while attempting to perform an operation When the upstream machine is failed in mode u_i , it can get repaired during a time unit with probability r_{u_i} Similarly p_{d_j} and r_{d_j} represent respectively failure and repair probabilities

How Much is it Costing Your Business to Run Old PCs?

Techaisle study found that an average of 42 productive work hours a year is lost while older computers are being repaired, versus 21 hours of annual repair time for PCs less than 4 years old—twice as much downtime But this is just part of the time that old PCs can consume

perfectly reliable machines * operation time of the line is equal to the operation time of the slowest machine, so the Since the system produces one part per time unit while it is working, it produces U during the interval of length t Note that, approximately, $P_i(t)$ = probability that M_i is repaired, while it is down, $(t, t + \delta t)$

Solution: Let $X(t)$ be the number of machines operating at time t Note that $\{X(t)\}$ is a continuous time Markov chain with states $\{0, 1, 2\}$ and rates $q_{01} = q_{12} = \lambda$, $q_{02} = q_{20} = 0$, $q_{21} = 2\mu$, $q_{10} = \mu$ This can be recognized as a birth/death process, so the limiting probabilities satisfy detailed balance: $\lambda P_0 = \mu P_1$, $\lambda P_1 = 2\mu P_2$ Since
